<b>2</b>	Least Squares Estimation and Its Properties	<b>2</b>
3	Gaussian Noise	7

Let us review<sup>1</sup>.

# 1 Basic Model Assumptions (without Gaussian Noise)

We model one continuous response variable, as a linear function of p numerical predictors, plus noise:

$$Y = \beta_0 + \beta_1 X_1 + \dots + \beta_p X_p + \epsilon \tag{1}$$

Linearity is an assumption, which can be wrong.

Further assumptions take the form of restrictions on the noise:

$$\mathbb{E}\left[\epsilon|X\right] = 0 \tag{2}$$

$$\operatorname{Var}\left[\epsilon|X\right] = \sigma^2 \tag{3}$$

(4)

Moreover, we assume  $\epsilon$  is uncorrelated across observations.

We convert this to matrix form:

$$\mathbf{Y} = \mathbf{x}\boldsymbol{\beta} + \boldsymbol{\epsilon} \tag{5}$$

<sup>&</sup>lt;sup>1</sup>All of the theory for simple linear regression is a special case of what follows, with p = 1. The entire first third of the course was just a warm-up period.

**Y** is an  $n \times 1$  matrix of random variables; **x** is an  $n \times (p+1)$  matrix, with an extra column of all 1s;  $\epsilon$  is an  $n \times 1$  matrix. Beyond linearity, the assumptions translate to

$$\mathbb{E}\left[\epsilon|\mathbf{x}\right] = \mathbf{0} \tag{6}$$

and

$$\operatorname{Var}\left[\epsilon|\mathbf{x}\right] = \sigma^2 \mathbf{I} \tag{7}$$

We don't know  $\beta$ . If we guess it is **b**, we will make an  $n \times 1$  vector of predictions

and have an  $n\times 1$  vector of errors

$$\mathbf{y} - \mathbf{x}\mathbf{b} \tag{9}$$

The mean squared error, as a function of **b**, is then

$$MSE(\mathbf{b}) = \frac{1}{n} (\mathbf{y} - \mathbf{x}\mathbf{b})^T (\mathbf{y} - \mathbf{x}\mathbf{b})$$
(10)

### 2 Least Squares Estimation and Its Properties

The least squares estimate of the coefficients is the one which minimizes the MSE:

$$\widehat{\beta} \equiv \underset{\mathbf{b}}{\operatorname{argmin}} MSE(\mathbf{b}) \tag{11}$$

To find this, we need the derivatives:

$$\nabla_{\mathbf{b}} MSE = \frac{2}{n} (\mathbf{x}^T \mathbf{y} - \mathbf{x}^T \mathbf{x} \mathbf{b})$$
(12)

We set the derivative to zero at the optimum:

$$\frac{1}{n}\mathbf{x}^{T}\left(\mathbf{y}-\mathbf{x}\widehat{\beta}\right)=\mathbf{0}$$
(13)

The term in parentheses is the vector of errors when we use the least-squares estimate. This is the vector of residuals,

$$\mathbf{e} \equiv \mathbf{y} - \mathbf{x}\widehat{\boldsymbol{\beta}} \tag{14}$$

so the have the **normal**, **estimating** or **score** equations,

$$\frac{1}{n}\mathbf{x}^{T}\mathbf{e} = \mathbf{0} \tag{15}$$

We say "equations", plural, because this is equivalent to the set of p+1 equations

$$\frac{1}{n}\sum_{i=1}^{n}e_{i} = 0 (16)$$

$$\frac{1}{n} \sum_{i=1}^{n} e_i x_{ij} = 0 \tag{17}$$

02:20 Friday  $13^{\text{th}}$  November, 2015

(Many people omit the factor of 1/n.) This tells us that while **e** is an *n*-dimensional vector, it is subject to p+1 linear constraints, so it is confined to a linear subspace of dimension n-p-1. Thus n-p-1 is the number of **residual degrees of freedom**.

The solution to the estimating equations is

$$\widehat{\beta} = (\mathbf{x}^T \mathbf{x})^{-1} \mathbf{x}^T \mathbf{y} \tag{18}$$

This is one of the two most important equations in the whole subject. It says that the coefficients are a linear function of the response vector  $\mathbf{y}$ . Set all the responses to 0 and all the coefficients are zero; double all the responses and all the coefficients are doubled.

Say that  $\mathbf{x}'$  is the  $n \times p$  matrix of predictors, without the column of 1s, and  $\beta'$  is the  $p \times 1$  vector of slopes. Finally, let  $\overline{\mathbf{x}}$  be the  $1 \times p$  vector of the mean values of the predictors. Then

$$\hat{\beta}_0 = \overline{y} - \overline{\mathbf{x}}\hat{\beta}' \tag{19}$$

while

$$\widehat{\beta}' = \widehat{\operatorname{Var}} \left[ X \right]^{-1} \widehat{\operatorname{Cov}} \left[ X, Y \right]$$
(20)

just as in simple linear regression.

The least squares estimate is always a constant plus noise:

$$\widehat{\boldsymbol{\beta}} = (\mathbf{x}^T \mathbf{x})^{-1} \mathbf{x}^T \mathbf{Y}$$
(21)

$$= (\mathbf{x}^T \mathbf{x})^{-1} \mathbf{x}^T (\mathbf{x}\beta + \epsilon)$$
(22)

$$= (\mathbf{x}^T \mathbf{x})^{-1} \mathbf{x}^T \mathbf{x} \beta + (\mathbf{x}^T \mathbf{x})^{-1} \mathbf{x}^T \epsilon$$
(23)

$$= \beta + (\mathbf{x}^T \mathbf{x})^{-1} \mathbf{x}^T \epsilon \tag{24}$$

The least squares estimate is always unbiased:

$$\mathbb{E}\left[\widehat{\beta}\right] = \beta + (\mathbf{x}^T \mathbf{x})^{-1} \mathbf{x}^T \mathbb{E}\left[\epsilon\right] = \beta$$
(25)

Its variance always depends just on  $\sigma^2$  and  $\mathbf{x}^T \mathbf{x}$ :

$$\operatorname{Var}\left[\widehat{\beta}\right] = \sigma^2 (\mathbf{x}^T \mathbf{x})^{-1} \tag{26}$$

Since the entries in  $\mathbf{x}^T \mathbf{x}$  are usual proportional to n, it can be helpful to say

$$\operatorname{Var}\left[\widehat{\beta}\right] = \frac{\sigma^2}{n} \left(\frac{1}{n} \mathbf{x}^T \mathbf{x}\right)^{-1}$$
(27)

The variance of any one coefficient estimator is

$$\operatorname{Var}\left[\hat{\beta}_{i}\right] = \frac{\sigma^{2}}{n} \left(\frac{1}{n} \mathbf{x}^{T} \mathbf{x}\right)_{i+1,i+1}^{-1}$$
(28)

The vector of fitted means or conditional values is

$$\widehat{\mathbf{m}} \equiv \mathbf{x}\widehat{\boldsymbol{\beta}} \tag{29}$$

This is more conveniently expressed in terms of the original matrices:

$$\widehat{\mathbf{m}} = \mathbf{x} (\mathbf{x}^T \mathbf{x})^{-1} \mathbf{x}^T \mathbf{y} = \mathbf{H} \mathbf{y}$$
(30)

The fitted values are thus linear in **y**: set the responses all to zero and all the fitted values will be zero; double all the responses and all the fitted values will double.

The  $n \times n$  hat matrix  $H \equiv \mathbf{x}(\mathbf{x}^T \mathbf{x})^{-1} \mathbf{x}^T$ , also called the influence, projection or prediction matrix, controls the fitted values. It is a function of  $\mathbf{x}$  alone, ignoring the response variable totally. It is an  $n \times n$  matrix with several important properties:

- It is symmetric,  $\mathbf{H}^T = \mathbf{H}$ .
- It is idempotent,  $\mathbf{H}^2 = \mathbf{H}$ .
- Its trace tr  $\mathbf{H} = \sum_{i} H_{ii} = p + 1$ , the number of degrees of freedom for the fitted values.

The variance-covariance matrix of the fitted values is

$$\operatorname{Var}\left[\widehat{\mathbf{m}}\right] = \mathbf{H}\sigma^{2}\mathbf{I}\mathbf{H}^{T} = \sigma^{2}\mathbf{H}$$
(31)

To make a prediction at a new point, not in the data used for estimation, we take its predictor coordinates and group them into a  $1 \times (p+1)$  matrix  $\mathbf{x}_{new}$  (including the 1 for the intercept). The point prediction for Y is then  $\mathbf{x}_{new}\hat{\beta}$ . The expected value is  $\mathbf{x}_{new}\beta$ , and the variance is  $\operatorname{Var}\left[\mathbf{x}_{new}\hat{\beta}\right] = \mathbf{x}_{new}\operatorname{Var}\left[\hat{\beta}\right]\mathbf{x}_{new}^{T} = \sigma^{2}\mathbf{x}_{new}(\mathbf{x}^{T}\mathbf{x})^{-1}\mathbf{x}_{new}^{T}$ .

The residuals are also linear in the response:

$$\mathbf{e} \equiv \mathbf{y} - \widehat{\mathbf{m}} = (\mathbf{I} - \mathbf{H})\mathbf{y} \tag{32}$$

The trace of  $\mathbf{I} - \mathbf{H}$  is n - p - 1. The variance-covariance matrix of the residuals is thus

$$\operatorname{Var}\left[\mathbf{e}\right] = \sigma^{2}(\mathbf{I} - \mathbf{H}) \tag{33}$$

The mean squared error is

$$MSE = \frac{1}{n} \sum_{i=1}^{n} e_i^2 = \frac{1}{n} \mathbf{e}^T \mathbf{e}$$
(34)

Its expectation value is slightly below  $\sigma^2$ :

$$\mathbb{E}\left[MSE\right] = \sigma^2 \frac{n-p-1}{n} \tag{35}$$

(This may be proved using the trace of  $\mathbf{I} - \mathbf{H}$ .) An unbiased estimate of  $\sigma^2$ , which I will call  $\hat{\sigma}^2$  throughout the rest of this, is

$$\hat{\sigma}^2 \equiv MSE \frac{n}{n-p-1} \tag{36}$$

The **leverage** of data point i is  $H_{ii}$ . This has several interpretations:

- 1. Var  $[\hat{m}_i] = \sigma^2 H_{ii}$ ; the leverage controls how much variance there is in the fitted value.
- 2.  $\partial \hat{m}_i / \partial y_i = H_{ii}$ ; the leverage says how much changing the response value for point *i* changes the fitted value there.
- 3. Cov  $[\hat{m}_i, Y_i] = \sigma^2 H_{ii}$ ; the leverage says how much covariance there is between the *i*<sup>th</sup> response and the *i*<sup>th</sup> fitted value.
- 4. Var  $[e_i] = \sigma^2 (1 H_{ii})$ ; the leverage controls how big the *i*<sup>th</sup> residual is.

The standardized residual is

$$r_i = \frac{e_i}{\hat{\sigma}\sqrt{1 - H_{ii}}} \tag{37}$$

so all the standardized residuals have the same variance.

The only restriction we have to impose on the predictor variables  $X_i$  is that  $(\mathbf{x}^T \mathbf{x})^{-1}$  needs to exist. This is equivalent to

- **x** is not **collinear**: none of its columns is a linear combination of other columns; which is also equivalent to
- The eigenvalues of  $\mathbf{x}^T \mathbf{x}$  are all > 0. (If there are zero eigenvalues, the corresponding eigenvectors indicate linearly-dependent combinations of predictor variables.)

Nearly-collinear predictor variables tend to lead to large variances for coefficient estimates, with high levels of correlation among the estimates. Sometimes this uncertainty can be reduced by finding new variables which contain most (or all) of the same information, but are less correlated with each other.

It is perfectly OK for one column of  $\mathbf{x}$  to be a function of another, provided it is a nonlinear function. Thus in **polynomial** regression we add extra columns for powers of one or more of the predictor variables. (Any other nonlinear function is however also legitimate.) This complicates the interpretation of coefficients as slopes, just as though we had done a transformation of a column; see the handout on transformations. Estimation and inference for the coefficients on these predictor variables goes exactly like estimation and inference for any other coefficient.

One column of  $\mathbf{x}$  could be a (nonlinear) function of two or more of the other columns; this is how we represent **interactions**. Usually the interaction column is just a product of two other columns, for a **product** or **multiplicative** 

interaction; this also complicates the interpretation of coefficients as slopes. (See the notes on interactions.) Estimation and inference for the coefficients on these predictor variables goes exactly like estimation and inference for any other coefficient.

We can include qualitative predictor variables with k discrete categories or levels by introducing binary indicator variables for k-1 of the levels, and adding them to **x**. The coefficients on these indicators tell us about amounts that are added (or subtracted) to the response for every individual who is a member of that category or level, compared to what would be predicted for an otherwiseidentical individual in the baseline category. Equivalently, every category gets its own intercept. Estimation and inference for the coefficients on these predictor variables goes exactly like estimation and inference for any other coefficient.

Interacting the indicator variables for categories with other variables gives coefficients which say what amount is added to the *slope* used for each member of that category (compared to the slope for members of the baseline level). Equivalently, each category gets its own slope. Estimation and inference for the coefficients on these predictor variables goes exactly like estimation and inference for any other coefficient.

Model selection for prediction aims at picking a model which will predict well on new data drawn from the same distribution as the data we've seen. One way to estimate this out-of-sample performance is to look at what the expected squared error would be on new data with the same  $\mathbf{x}$  matrix, but a new, independent realization of  $\mathbf{y}$ . In the notes on model selection, we showed that

$$\mathbb{E}\left[\frac{1}{n}(\mathbf{Y}'-\widehat{m})^{T}(\mathbf{Y}'-\widehat{m})\right] = \mathbb{E}\left[\frac{1}{n}(\mathbf{Y}-\widehat{m})^{T}(\mathbf{Y}-\widehat{m})\right] + 2\frac{1}{n}\sum_{i=1}^{n}\operatorname{Cov}\left[Y_{i}(\mathbf{3})\right]$$
$$= \mathbb{E}\left[\frac{1}{n}(\mathbf{Y}-\widehat{m})^{T}(\mathbf{Y}-\widehat{m})\right] + \frac{2}{n}\sigma^{2}\operatorname{tr}H \qquad (39)$$

$$= \mathbb{E}\left[\frac{1}{n}(\mathbf{Y}-\widehat{m})^{T}(\mathbf{Y}-\widehat{m})\right] + \frac{2}{n}\sigma^{2}(p+1) \quad (40)$$

Mallow's  $C_p$  estimates this by

=

$$MSE + \frac{2}{n}\hat{\sigma}^2(p+1) \tag{41}$$

using the  $\hat{\sigma}^2$  from the largest, model being selected among (which includes all the other models as special cases).

An alternative is leave-one-out cross-validation, which amounts to

$$\frac{1}{n}\sum_{i=1}^{n}\left(\frac{e_i}{1-H_{ii}}\right)^2\tag{42}$$

 $C_P$  and LOOCV converge for large n.

02:20 Friday  $13^{\text{th}}$  November, 2015

#### 3 Gaussian Noise

The Gaussian noise assumption is added on to the other assumptions already made. It is that  $\epsilon_i \sim N(0, \sigma^2)$ , independent of the predictor variables and all other  $\epsilon_j$ . Said otherwise,  $\epsilon$  has a multivariate Gaussian distribution,

$$\epsilon \sim MVN(\mathbf{0}, \sigma^2 \mathbf{I}) \tag{43}$$

Under this assumption, it follows that, since  $\hat{\beta}$  is a linear function of  $\epsilon$ , it also has a multivariate Gaussian distribution:

$$\widehat{\beta} \sim MVN(\beta, \sigma^2 (\mathbf{x}^T \mathbf{x})^{-1})$$
(44)

Also,

$$\widehat{\mathbf{m}} \sim MVN(\mathbf{x}\beta, \sigma^2 \mathbf{H}) \tag{45}$$

It follows from this that

$$\widehat{\beta}_i \sim N(\beta_i, \sigma^2(\mathbf{x}^T \mathbf{x})_{i+1, i+1}^{-1}$$
(46)

and

$$\widehat{m}_i \sim N(\mathbf{x}_i \beta, \sigma^2 H_{ii}) \tag{47}$$

The sampling distribution of the estimated conditional mean at a new point  $\mathbf{x}_{new}$  is  $N(\mathbf{x}_{new}\beta, \sigma^2 \mathbf{x}_{new}(\mathbf{x}^T \mathbf{x})^{-1} \mathbf{x}_{new}^T)$ . The mean squared error follows a  $\chi^2$ -ish distribution:

$$\frac{nMSE}{\sigma^2} \sim \chi^2_{n-p-1} \tag{48}$$

Moreover, the MSE is statistically independent of  $\hat{\beta}$ . We may therefore define

$$\widehat{\mathrm{se}}\left[\widehat{\beta}_{i}\right] = \widehat{\sigma}\sqrt{(\mathbf{x}^{T}\mathbf{x})_{i+1,i+1}^{-1}}$$
(49)

and

$$\widehat{\operatorname{se}}\left[\widehat{m}_{i}\right] = \widehat{\sigma}\sqrt{H_{ii}} \tag{50}$$

and get t distributions:

$$\frac{\hat{\beta}_i - \beta_i}{\widehat{\operatorname{se}}\left[\hat{\beta}_i\right]} \sim t_{n-p-1} \tag{51}$$

and

$$\frac{\hat{m}_i - m_i}{\widehat{\operatorname{se}}\left[\hat{m}_i\right]} \sim t_{n-p-1} \tag{52}$$

The **Wald test** for the hypothesis that  $\beta_i = \beta_i^*$  therefore forms the test statistic

$$\frac{\beta_i - \beta_i^*}{\widehat{\operatorname{se}}\left[\hat{\beta}_i\right]} \tag{53}$$

and rejects the hypothesis if it is too large (above or below zero) compared to the quantiles of a  $t_{n-p-1}$  distribution. The summary function of R runs such a test of the hypothesis that  $\beta_i = 0$ . There is nothing magic or even especially important about testing for a 0 coefficient, and the same test works for testing whether a slope = 42 (for example).

Important! The null hypothesis being test is

Y is a linear function of  $X_1, \ldots X_p$ , and of no other predictor variables, with independent, constant-variance Gaussian noise, and the coefficient  $\beta_i = 0$  exactly.

and the alternative hypothesis is

Y is a linear function of  $X_1, \ldots X_p$ , and of no other predictor variables, with independent, constant-variance Gaussian noise, and the coefficient  $\beta_i \neq 0$ .

The Wald test does not test any of the model assumptions (it presumes them all), and it cannot say whether in an absolutely sense  $X_i$  matters for Y; adding or removing other predictors can change whether the true  $\beta_i = 0$ .

Warning! Retaining the null hypothesis  $\beta_i = 0$  can happen if either the parameter is precisely estimated, and confidently known to be close to zero, or if it is *im*-precisely estimated, and might as well be zero or something huge on either side. Saying "We can ignore this because we can be quite sure it's small" can make sense; saying "We can ignore this because we have no idea what it is" is preposterous.

To test whether several coefficients are all simultaneously zero, use an F test. The null hypothesis is

Y is a linear function of  $X_1, \ldots, X_p$ , and of no other predictor variables, with independent, constant-variance Gaussian noise, and the coefficients for all but q of the variables are exactly 0,  $\beta_{q+1} = \beta_{q+2} \ldots \beta_p = 0$ .

(You can always re-order the predictor variables so that you're saying coefficients 1 through q are free, and q + 1 through p are fixed to zero.) The alternative hypothesis is

Y is a linear function of  $X_1, \ldots X_p$ , and of no other predictor variables, with independent, constant-variance Gaussian noise, and the coefficient  $\beta_{q+1}, \beta_{q+2}, \ldots \beta_q \neq 0$ .

The smaller, null model leads to an estimate of  $\sigma^2$ ,  $\hat{\sigma}^2_{null}$ , and the larger, alternative model gives us the estimate  $\hat{\sigma}^2_{full}$ . The *F* statistic is

$$F_{stat} = \frac{(\hat{\sigma}_{null}^2 - \hat{\sigma}_{full}^2)/(p-q)}{\hat{\sigma}_{full}^2/(n-p-1)}$$
(54)

The numerator is basically about how much the MSE shrinks for each extra parameter we throw at fitting the data; the denominator is an estimate of how big

an improvement-per-degree-of-freedom we should see under the null hypothesis. Under that null hypothesis,

$$F_{stat} \sim F_{p-q,n-p-1} \tag{55}$$

Note that the F test when q = p - 1 becomes identical to a t-test.

If 0 < q < p, we have a "partial" F test. A "full" F test sets q = 0, i.e., it tests the null hypothesis of an intercept-only model (with independent, constant-variance Gaussian noise) against the alternative of the linear model on  $X_1, \ldots X_p$  (and only those variables, with independent, constant-variance Gaussian noise). This is only of interest under very unusual circumstances.

Once again, no F test is capable of checking any modeling assumptions. This is because both the null hypothesis and the alternative hypothesis presume that the all of the modeling assumptions are exactly correct.

Inverting the Wald test yields confidence intervals for each coefficient: a  $1-\alpha$  confidence interval for  $\beta_i$  is

$$\hat{\beta}_i \pm \hat{\operatorname{se}} \left[\beta_i\right] t_{n-p-1}(\alpha/2) \tag{56}$$

Inverting the F test leads to ellipse-shaped (in more than two dimensions, "ellipsoidal") confidence regions. (See Lecture 18 for the detailed formula, which involves matrix inversion.) These make a *simultaneous* guarantee: either all the parameters are inside the confidence region, or we were very unlucky when we got our data. A simpler way to get a simultaneous confidence region for all p parameters is to use  $1 - \alpha/p$  confidence intervals for each one ("Bonferroni correction").

Turning to the fitted values, by entirely parallel reasoning, we may test any hypothesis of the form  $m_i = m_i^*$  by a *t*-test. More practically, a  $1 - \alpha$  confidence interval for the fitted value (conditional expectation) is

$$\hat{m}_i \pm \hat{\mathrm{se}} \left[ \hat{m}_i \right] t_{n-p-1}(\alpha/2) \tag{57}$$

The standardized residuals do not quite have a t distribution, because  $\hat{\sigma}$  is a function of all the  $e_i$ s, hence the numerator in the definition of  $r_i$  is not independent of the denominator. But the cross-validated or studentized residuals are:

- 1. Temporarily hold out data point i
- 2. Re-estimate the coefficients to get  $\hat{\beta}^{(-i)}$  and  $\hat{\sigma}^{(-i)}$
- 3. Make a prediction for  $y_i$ ,  $\hat{m}_i^{(-i)}$
- 4. Calculate

$$t_{i} = \frac{y_{i} - \hat{m}_{i}^{(-i)}}{\hat{\sigma}^{(-i)} + \hat{s} \hat{e} \left[ \hat{m}_{i}^{(-i)} \right]}$$
(58)

This can be done without recourse to actually re-fitting the model<sup>2</sup>:

$$t_{i} = r_{i} \sqrt{\frac{n-p-1}{n-p-r_{i}^{2}}}$$
(59)

(Note that for large n, this is typically extremely close to  $r_i$ .) Once we have it, there is a sampling distribution<sup>3</sup> for  $t_i$ :

$$t_i \sim t_{n-p-2} \tag{60}$$

(The -2 is because we're using n-1 data points to estimate p+1 coefficients.)

Cook's distance for point i is the sum of the (squared) changes to all the fitted values if i was omitted; it is<sup>4</sup>

$$D_i = \frac{1}{p+1} e_i^2 \frac{H_{ii}}{(1-H_{ii})^2} \tag{61}$$

There is a tradition of being worried if  $D_i \ge F_{p,n-p-2}(0.1)$ , but no hard proofs behind it.

Under the Gaussian assumption, one can calculate a likelihood for the data. The log-likelihood is, up to constants independent of the parameters,

$$L = -\frac{n}{2}\log MSE \tag{62}$$

since the MSE is the maximum likelihood estimate of  $\sigma^2$  (even though it is slightly biased). The likelihood ratio test which can be used in place of the F test has as its test statistic

$$\Lambda \equiv \log \frac{L_{full}}{L_{null}} \tag{63}$$

$$= \log L_{full} - \log L_{null} \tag{64}$$

$$= \frac{n}{2} \left( -\log MSE_{full} + \log MSE_{null} \right) \tag{65}$$

$$= \frac{n}{2} \log \frac{MSE_{null}}{MSE_{full}} \tag{66}$$

Under the null hypothesis,  $2\Lambda \sim \chi^2_{p-q}$  for large *n*.

The log-likelihood can also be used to calculate a model selection criterion, the Akaike information criterion (AIC):

$$AIC = L - (p+1) \tag{67}$$

Sometimes this is written with a factor of 2, or of -1 (so that smaller values of AIC are preferred), or of -2 (ditto). As  $n \to \infty$ , the model selected by AIC becomes identical to the model selected by  $C_p$  or LOOCV. (In fact, the AIC score of the true model converges on its  $C_p$  or LOOCV score.) AIC is best thought of as a very fast (because very simple) approximation to leave-one-out CV.

 $<sup>^2\</sup>mathrm{Like}$  the definition of cross-validated or studentized residuals, this next formula does not need the Gaussian noise assumption.

<sup>&</sup>lt;sup>3</sup>Under the Gaussian noise assumption.

<sup>&</sup>lt;sup>4</sup>Again, no Gaussian noise assumption is needed for the next formula.
