

Chapter 19

Factor Analysis

19.1 From PCA to Factor Analysis

Let's sum up PCA. We start with n different p -dimensional vectors as our data, i.e., each observation as p numerical variables. We want to reduce the number of dimensions to something more manageable, say q . The principal components of the data are the q orthogonal directions of greatest variance in the original p -dimensional space; they can be found by taking the top q eigenvectors of the sample covariance matrix. Principal components analysis summarizes the data vectors by projecting them on to the principal components.

All of this is purely an algebraic undertaking; it involves no probabilistic assumptions whatsoever. It also supports no statistical inferences — saying nothing about the population or stochastic process which made the data, it just summarizes the data. How can we add some probability, and so some statistics? And what does that let us do?

Start with some notation. \mathbf{X} is our data matrix, with n rows for the different observations and p columns for the different variables, so X_{ij} is the value of variable j in observation i . Each principal component is a vector of length p , and there are p of them, so we can stack them together into a $p \times p$ matrix, say \mathbf{w} . Finally, each data vector has a projection on to each principal component, which we collect into an $n \times p$ matrix \mathbf{F} . Then

$$\begin{aligned} \mathbf{X} &= \mathbf{F}\mathbf{w} && (19.1) \\ [n \times p] &= [n \times p][p \times p] \end{aligned}$$

where I've checked the dimensions of the matrices underneath. This is an exact equation involving no noise, approximation or error, but it's kind of useless; we've replaced p -dimensional vectors in \mathbf{X} with p -dimensional vectors in \mathbf{F} . If we keep only to $q < p$ largest principal components, that corresponds to dropping columns from

\mathbf{F} and rows from \mathbf{w} . Let's say that the truncated matrices are \mathbf{F}_q and \mathbf{w}_q . Then

$$\begin{aligned} \mathbf{X} &\approx \mathbf{F}_q \mathbf{w}_q & (19.2) \\ [n \times p] &= [n \times q][q \times p] \end{aligned}$$

The error of approximation — the difference between the left- and right- hand-sides of Eq. 19.2 — will get smaller as we increase q . (The line below the equation is a sanity-check that the matrices are the right size, which they are. Also, at this point the subscript qs get too annoying, so I'll drop them.) We can of course make the two sides match exactly by adding an error or residual term on the right:

$$\mathbf{X} = \mathbf{F}\mathbf{w} + \epsilon \quad (19.3)$$

where ϵ has to be an $n \times p$ matrix.

Now, Eq. 19.3 should look more or less familiar to you from regression. On the left-hand side we have a measured outcome variable (\mathbf{X}), and on the right-hand side we have a systematic prediction term ($\mathbf{F}\mathbf{w}$) plus a residual (ϵ). Let's run with this analogy, and start treating ϵ as *noise*, as a random variable which has got some distribution, rather than whatever arithmetic says is needed to balance the two sides. (This move is the difference between just drawing a straight line through a scatter plot, and inferring a linear regression.) Then \mathbf{X} will also be a random variable. When we want to talk about the random variable which goes in the i^{th} column of \mathbf{X} , we'll call it X_i .

What about \mathbf{F} ? Well, in the analogy it corresponds to the independent variables in the regression, which ordinarily we treat as fixed rather than random, but that's because we actually get to observe them; here we don't, so it will make sense to treat \mathbf{F} , too, as random. Now that they are random variables, we say that we have q **factors**, rather than components, that \mathbf{F} is the matrix of **factor scores** and \mathbf{w} is the matrix of **factor loadings**. The variables in \mathbf{X} are called **observable** or **manifest** variables, those in \mathbf{F} are **hidden** or **latent**. (Technically ϵ is also latent.)

Before we can actually do much with this model, we need to say more about the distributions of these random variables. The traditional choices are as follows.

1. All of the observable random variables X_i have mean zero and variance 1.
2. All of the latent factors have mean zero and variance 1.
3. The noise terms ϵ all have mean zero.
4. The factors are uncorrelated across individuals (rows of \mathbf{F}) and across variables (columns).
5. The noise terms are uncorrelated across individuals, and across observable variables.
6. The noise terms are uncorrelated with the factor variables.

Item (1) isn't restrictive, because we can always center and standardize our data. Item (2) isn't restrictive either — we could always center and standardize the factor variables without really changing anything. Item (3) actually follows from (1) and (2). The substantive assumptions — the ones which will give us predictive power but could also go wrong, and so really define the factor model — are the others, about lack of correlation. Where do they come from?

Remember what the model looks like:

$$\mathbf{X} = \mathbf{F}\mathbf{w} + \epsilon \quad (19.4)$$

All of the systematic patterns in the observations \mathbf{X} should come from the first term on the right-hand side. The residual term ϵ should, if the model is working, be unpredictable noise. Items (3) through (5) express a very strong form of this idea. In particular it's vital that the noise be uncorrelated with the factor scores.

19.1.1 Preserving correlations

There is another route from PCA to the factor model, which many people like but which I find less compelling; it starts by changing the objectives.

PCA aims to minimize the mean-squared distance from the data to their projects, or what comes to the same thing, to preserve variance. But it doesn't preserve correlations. That is, the correlations of the features of the image vectors are not the same as the correlations among the features of the original vectors (unless $q = p$, and we're not really doing any data reduction). We might value those correlations, however, and want to preserve them, rather than the than trying to approximate the actual data.¹ That is, we might ask for a set of vectors whose image in the feature space will have the same correlation matrix as the original vectors, or as close to the same correlation matrix as possible while still reducing the number of dimensions. This leads to the factor model we've already reached, as we'll see.

19.2 The Graphical Model

It's common to represent factor models visually, as in Figure 19.1. This is an example of a **graphical model**, in which the nodes or vertices of the graph represent random variables, and the edges of the graph represent direct statistical dependencies between the variables. The figure shows the observables or features in square boxes, to indicate that they are manifest variables we can actually measure; above them are the factors, drawn in round bubbles to show that we don't get to see them. The fact that there are no direct linkages between the factors shows that they are independent of one another. From below we have the noise terms, one to an observable.

¹Why? Well, originally the answer was that the correlation coefficient had just been invented, and was about the only way people had of measuring relationships between variables. Since then it's been propagated by statistics courses where it is the only way people are *taught* to measure relationships. The great statistician John Tukey once wrote "Does anyone know when the correlation coefficient is useful, as opposed to when it is used? If so, why not tell us?" (Tukey, 1954, p. 721).

Figure 19.1: Graphical model form of a factor model. Circles stand for the unobserved variables (factors above, noises below), boxes for the observed features. Edges indicate non-zero coefficients — entries in the factor loading matrix \mathbf{w} , or specific variances ψ_i . Arrows representing entries in \mathbf{w} are decorated with those entries. Note that it is common to omit the noise variables in such diagrams, with the implicit understanding that every variable with an incoming arrow also has an incoming noise term.

Notice that not every observable is connected to every factor: this depicts the fact that some entries in \mathbf{w} are zero. In the figure, for instance, X_1 has an arrow only from F_1 and not the other factors; this means that while $w_{11} = 0.87$, $w_{21} = w_{31} = 0$.

Drawn this way, one sees how the factor model is **generative** — how it gives us a recipe for producing new data. In this case, it's: draw new, independent values for the factor scores F_1, F_2, \dots, F_q ; add these up with weights from \mathbf{w} ; and then add on the final noises $\epsilon_1, \epsilon_2, \dots, \epsilon_p$. If the model is right, this is a procedure for generating new, synthetic data with the same characteristics as the real data. In fact, it's a story about how the real data came to be — that there really are some latent variables (the factor scores) which linearly cause the observables to have the values they do.

19.2.1 Observables Are Correlated Through the Factors

One of the most important consequences of the factor model is that observable variables are correlated with each other *solely* because they are correlated with the hidden factors. To see how this works, take X_1 and X_2 from the diagram, and let's calculate their covariance. (Since they both have variance 1, this is the same as their correlation.)

$$\text{Cov}[X_1, X_2] = \mathbf{E}[X_1 X_2] - \mathbf{E}[X_1] \mathbf{E}[X_2] \quad (19.5)$$

$$= \mathbf{E}[X_1 X_2] \quad (19.6)$$

$$= \mathbf{E}[(F_1 w_{11} + F_2 w_{21} + \epsilon_1)(F_1 w_{12} + F_2 w_{22} + \epsilon_2)] \quad (19.7)$$

$$\begin{aligned} &= \mathbf{E} \left[F_1^2 w_{11} w_{12} + F_1 F_2 (w_{11} w_{22} + w_{21} w_{12}) + F_2^2 w_{21} w_{22} \right] \\ &\quad + \mathbf{E}[\epsilon_1 \epsilon_2] + \mathbf{E}[\epsilon_1 (F_1 w_{12} + F_2 w_{22})] \\ &\quad + \mathbf{E}[\epsilon_2 (F_1 w_{11} + F_2 w_{21})] \end{aligned} \quad (19.8)$$

Since the noise terms are uncorrelated with the factor scores, and the noise terms for different variables are uncorrelated with each other, *all* the terms containing ϵ s have expectation zero. Also, F_1 and F_2 are uncorrelated, so

$$\text{Cov}[X_1, X_2] = \mathbf{E}[F_1^2] w_{11} w_{12} + \mathbf{E}[F_2^2] w_{21} w_{22} \quad (19.9)$$

$$= w_{11} w_{12} + w_{21} w_{22} \quad (19.10)$$

using the fact that the factors are scaled to have variance 1. This says that the covariance between X_1 and X_2 is what they have from both correlating with F_1 , plus what they have from both correlating with F_2 ; if we had more factors we would add on $w_{31} w_{32} + w_{41} w_{42} + \dots$ out to $w_{q1} w_{q2}$. And of course this would apply as well to any other pair of observable variables. So the general form is

$$\text{Cov}[X_i, X_j] = \sum_{k=1}^q w_{ki} w_{kj} \quad (19.11)$$

so long as $i \neq j$.

The jargon says that observable i **loads on** factor k when $w_{ki} \neq 0$. If two observables do not load on to any of the same factors, if they do not share any common factors, then they will be independent. If we could condition on (“control for”) the factors, all of the observables would be conditionally independent.

Graphically, we draw an arrow from a factor node to an observable node if and only if the observable loads on the factor. So then we can just *see* that two observables are correlated if they both have in-coming arrows from the same factors. (To find the actual correlation, we multiply the weights on all the edges connecting the two observable nodes to the common factors; that's Eq. 19.11.) Conversely, even though the factors are marginally independent of each other, if two factors both send arrows to the same observable, then they are dependent conditional on that observable.²

²To see that this makes sense, suppose that $X_1 = F_1 w_{11} + F_2 w_{21} + \epsilon_1$. If we know the value of X_1 , we know what F_1, F_2 and ϵ_1 have to add up to, so they are conditionally dependent.

19.2.2 Geometry: Approximation by Hyper-planes

Each observation we take is a vector in a p -dimensional space; the factor model says that these vectors have certain geometric relations to each other — that the data has a certain shape. To see what that is, pretend for right now that we can turn off the noise terms ϵ . The loading matrix \mathbf{w} is a $q \times p$ matrix, so each row of \mathbf{w} is a vector in p -dimensional space; call these vectors $\vec{w}_1, \vec{w}_2, \dots, \vec{w}_q$. Without the noise, our observable vectors would be linear combinations of these vectors (with the factor scores saying how much each vector contributes to the combination). Since the factors are orthogonal to each other, we know that they span a q -dimensional sub-space of the p -dimensional space — a line if $q = 1$, a plane if $q = 2$, in general a hyper-plane. If the factor model is true and we turn off noise, we would find all the data lying *exactly* on this hyper-plane. Of course, *with* noise we expect that the data vectors will be scattered around the hyper-plane; how close depends on the variance of the noise. But this is still a rather specific prediction about the shape of the data.

A weaker prediction than “the data lie on a low-dimensional plane in the high-dimensional space” is “the data lie on some low-dimensional surface, possibly curved, in the high-dimensional space”; there are techniques for trying to recover such surfaces, which can work even when factor analysis fails. But they are more complicated than factor analysis and outside the scope of this class. (Take data mining.)

19.3 Roots of Factor Analysis in Causal Discovery

The roots of factor analysis go back to work by Charles Spearman just over a century ago (Spearman, 1904); he was trying to discover the hidden structure of human intelligence. His observation was that schoolchildren’s grades in different subjects were all correlated with each other. He went beyond this to observe a particular *pattern* of correlations, which he thought he could explain as follows: the reason grades in math, English, history, etc., are all correlated is performance in these subjects is all correlated with *something else*, a general or **common** factor, which he named “general intelligence”, for which the natural symbol was of course g or G .

Put in a form like Eq. 19.4, Spearman’s model becomes

$$\mathbf{X} = \epsilon + \mathbf{G}\mathbf{w} \quad (19.12)$$

where \mathbf{G} is an $n \times 1$ matrix (i.e., a row vector) and \mathbf{w} is a $1 \times p$ matrix (i.e., a column vector). The correlation between feature i and G is just $w_i \equiv w_{1i}$, and, if $i \neq j$,

$$v_{ij} \equiv \text{Cov}[X_i, X_j] = w_i w_j \quad (19.13)$$

where I have introduced v_{ij} as a short-hand for the covariance.

Up to this point, this is all so much positing and assertion and hypothesis. What Spearman did next, though, was to observe that this hypothesis carried a very strong implication about the *ratios* of correlation coefficients. Pick any four distinct features,

i, j, k, l . Then, if the model (19.12) is true,

$$\frac{\mathbf{v}_{ij}/\mathbf{v}_{kj}}{\mathbf{v}_{il}/\mathbf{v}_{kl}} = \frac{\omega_i\omega_j/\omega_k\omega_j}{\omega_i\omega_l/\omega_k\omega_l} \quad (19.14)$$

$$= \frac{\omega_i/\omega_k}{\omega_i/\omega_k} \quad (19.15)$$

$$= 1 \quad (19.16)$$

The relationship

$$\mathbf{v}_{ij}\mathbf{v}_{kl} = \mathbf{v}_{il}\mathbf{v}_{kj} \quad (19.17)$$

is called the “tetrad equation”, and we will meet it again later when we consider methods for causal discovery in Part III. In Spearman’s model, this is one tetrad equation for every set of four distinct variables.

Spearman found that the tetrad equations held in his data on school grades (to a good approximation), and concluded that a single general factor of intelligence must exist. This was, of course, logically fallacious.

Later work, using large batteries of different kinds of intelligence tests, showed that the tetrad equations do not hold in general, or more exactly that departures from them are too big to explain away as sampling noise. (Recall that the equations are about the true correlations between the variables, but we only get to see sample correlations, which are always a little off.) The response, done in an *ad hoc* way by Spearman and his followers, and then more systematically by Thurstone, was to introduce *multiple* factors. This breaks the tetrad equation, but still accounts for the correlations among features by saying that features are really directly correlated with factors, and uncorrelated conditional on the factor scores.³ Thurstone’s form of factor analysis is basically the one people still use — there have been refinements, of course, but it’s mostly still his method.

19.4 Estimation

The factor model introduces a whole bunch of new variables to explain the observables: the factor scores \mathbf{F} , the factor loadings or weights \mathbf{w} , and the observable-specific variances ψ_i . The factor scores are specific to each individual, and individuals by assumption are independent, so we can’t expect them to really generalize. But the loadings \mathbf{w} are, supposedly, characteristic of the population. So it would be nice if we could separate estimating the population parameters from estimating the attributes of individuals; here’s how.

Since the variables are centered, we can write the covariance matrix in terms of the data frames:

$$\mathbf{v} = \mathbf{E} \left[\frac{1}{n} \mathbf{X}^T \mathbf{X} \right] \quad (19.18)$$

³You can (and should!) read the classic “The Vectors of Mind” paper (Thurstone, 1934) online.

(This is the true, population covariance matrix on the left.) But the factor model tells us that

$$\mathbf{X} = \mathbf{F}\mathbf{w} + \epsilon \quad (19.19)$$

This involves the factor scores \mathbf{F} , but remember that when we looked at the correlations between individual variables, those went away, so let's substitute Eq. 19.19 into Eq. 19.18 and see what happens:

$$\mathbf{E} \left[\frac{1}{n} \mathbf{X}^T \mathbf{X} \right] \quad (19.20)$$

$$= \frac{1}{n} \mathbf{E} \left[(\epsilon^T + \mathbf{w}^T \mathbf{F}^T) (\mathbf{F}\mathbf{w} + \epsilon) \right] \quad (19.21)$$

$$= \frac{1}{n} \left(\mathbf{E} \left[\epsilon^T \epsilon \right] + \mathbf{w}^T \mathbf{E} \left[\mathbf{F}^T \epsilon \right] + \mathbf{E} \left[\epsilon^T \mathbf{F} \right] \mathbf{w} + \mathbf{w}^T \mathbf{E} \left[\mathbf{F}^T \mathbf{F} \right] \mathbf{w} \right) \quad (19.22)$$

$$= \psi + 0 + 0 + \frac{1}{n} \mathbf{w}^T n \mathbf{I} \mathbf{w} \quad (19.23)$$

$$= \psi + \mathbf{w}^T \mathbf{w} \quad (19.24)$$

Behold:

$$\mathbf{v} = \psi + \mathbf{w}^T \mathbf{w} \quad (19.25)$$

The individual-specific variables \mathbf{F} have gone away, leaving only population parameters on both sides of the equation.

19.4.1 Degrees of Freedom

It only takes a bit of playing with Eq. 19.25 to realize that we are in trouble. Like any matrix equation, it represents a system of equations. How many equations in how many unknowns? Naively, we'd say that we have p^2 equations (one for each element of the matrix \mathbf{v}), and $p + pq$ unknowns (one for each diagonal element of ψ , plus one for each element of \mathbf{w}). If there are more equations than unknowns, then there is generally no solution; if there are fewer equations than unknowns, then there are generally infinitely many solutions. Either way, solving for \mathbf{w} seems hopeless (unless $q = p - 1$, in which case it's not very helpful). What to do?

Well, first let's do the book-keeping for degrees of freedom more carefully. The observable variables are scaled to have standard deviation one, so the diagonal entries of \mathbf{v} are all 1. Moreover, any covariance matrix is symmetric, so we are left with only $p(p-1)/2$ degrees of freedom in \mathbf{v} — only that many equations. On the other side, scaling to standard deviation 1 means we don't *really* need to solve separately for ψ — it's fixed as soon as we know what $\mathbf{w}^T \mathbf{w}$ is — which saves us p unknowns. Also, the entries in \mathbf{w} are not completely free to vary independently of each other, because each row has to be orthogonal to every other row. (Look back at the notes on PCA.) Since there are q rows, this gives us $q(q-1)/2$ constraints on \mathbf{w} — we can think of these as either extra equations, or as reductions in the number of free parameters (unknowns).⁴

⁴Notice that $\psi + \mathbf{w}^T \mathbf{w}$ is automatically symmetric, since ψ is diagonal, so we don't need to impose any extra constraints to get symmetry.

Summarizing, we really have $p(p-1)/2$ degrees of freedom in \mathbf{v} , and $pq - q(q-1)/2$ degrees of freedom in \mathbf{w} . If these two match, then there is (in general) a unique solution which will give us \mathbf{w} . But in general they will *not* be equal; then what? Let us consider the two cases.

More unknowns (free parameters) than equations (constraints) This is fairly straightforward: there is no unique solution to Eq. 19.25; instead there are *infinitely many* solutions. It's true that the loading matrix \mathbf{w} does have to satisfy some constraints, that not just any \mathbf{w} will work, so the data does give us some information, but there is a continuum of different parameter settings which all match the covariance matrix perfectly. (Notice that we are working with the population parameters here, so this isn't an issue of having only a limited sample.) There is just no way to use data to decide between these different parameters, to identify which one is right, so we say the model is **unidentifiable**. Most software for factor analysis, include R's `factanal` function, will check for this and just refuse to fit a model with too many factors relative to the number of observables.

More equations (constraints) than unknowns (free parameters) This is more interesting. In general, systems of equations like this are **overdetermined**, meaning that there is no way to satisfy all the constraints at once, and there isn't even a single solution. It's just not possible to write an arbitrary covariance matrix \mathbf{v} among, say, seven variables in terms of, say, a one-factor model (as $p(p-1)/2 = 7(7-1)/2 = 21 > 7(1) - 1(1-1)/2 = 7 = pq - q(q-1)/2$). But it *is* possible for special covariance matrices. In these situations, the factor model actually has testable implications for the data — it says that only certain covariance matrices are possible and not others. For example, we saw above that the one-factor model implies the tetrad equations must hold among the observable covariances; the constraints on \mathbf{v} for multiple-factor models are similar in kind but more complicated algebraically. By testing these implications, we can check whether or not the our favorite factor model is right.⁵

Now we don't know the true, population covariance matrix \mathbf{v} , but we can estimate it from data, getting an estimate $\hat{\mathbf{v}}$. The natural thing to do then is to equate this with the parameters and try to solve for the latter:

$$\hat{\mathbf{v}} = \hat{\boldsymbol{\psi}} + \hat{\mathbf{w}}^T \hat{\mathbf{w}} \quad (19.26)$$

The book-keeping for degrees of freedom here is the same as for Eq. 19.25. If q is too large relative to p , the model is unidentifiable; if it is too small, the matrix equation can only be solved if $\hat{\mathbf{v}}$ is of the right, restricted form, i.e., if the model is right. Of course even if the model is right, the sample covariances are the true covariances plus noise, so we shouldn't expect to get an *exact* match, but we can try in various way to minimize the discrepancy between the two sides of the equation.

⁵Actually, we need to be a little careful here. If we find that the tetrad equations don't hold, we know a one-factor model must be wrong. We could only conclude that the one-factor model must be right if we found that the tetrad equations held, *and* that there were no other models which implied those equations; but, as we'll see, there are.

19.4.2 A Clue from Spearman's One-Factor Model

Remember that in Spearman's model with a single general factor, the covariance between observables i and j in that model is the product of their factor weightings:

$$\mathbf{v}_{ij} = \omega_i \omega_j \quad (19.27)$$

The exception is that $\mathbf{v}_{ii} = \omega_i^2 + \phi_i$, rather than ω_i^2 . However, if we look at $\mathbf{u} = \mathbf{v} - \phi$, that's the same as \mathbf{v} off the diagonal, and a little algebra shows that its diagonal entries are, in fact, just ω_i^2 . So if we look at any two rows of \mathbf{U} , they're proportional to each other:

$$\mathbf{u}_{ij} = \frac{\omega_i}{\omega_k} \mathbf{u}_{kj} \quad (19.28)$$

This means that, when Spearman's model holds true, there is actually only *one* linearly-independent row in \mathbf{u} .

Recall from linear algebra that the **rank** of a matrix is how many linearly independent rows it has.⁶ Ordinarily, the matrix is of **full rank**, meaning all the rows are linearly independent. What we have just seen is that when Spearman's model holds, the matrix \mathbf{u} is *not* of full rank, but rather of rank 1. More generally, when the factor model holds with q factors, the matrix $\mathbf{u} = \mathbf{w}^T \mathbf{w}$ has rank q . The diagonal entries of \mathbf{u} , called the **common variances** or **commonalities**, are no longer automatically 1, but rather show how much of the variance in each observable is associated with the variances of the latent factors. Like \mathbf{v} , \mathbf{u} is a positive symmetric matrix.

Because \mathbf{u} is a positive symmetric matrix, we know from linear algebra that it can be written as

$$\mathbf{u} = \mathbf{c} \mathbf{d} \mathbf{c}^T \quad (19.29)$$

where \mathbf{c} is the matrix whose columns are the eigenvectors of \mathbf{u} , and \mathbf{d} is the diagonal matrix whose entries are the eigenvalues. That is, if we use all p eigenvectors, we can reproduce the covariance matrix exactly. Suppose we instead use \mathbf{c}_q , the $p \times q$ matrix whose columns are the eigenvectors going with the q largest eigenvalues, and likewise make \mathbf{d}_q the diagonal matrix of those eigenvalues. Then $\mathbf{c}_q \mathbf{d}_q \mathbf{c}_q^T$ will be a symmetric positive $p \times p$ matrix. This is a matrix of rank q , and so can only equal \mathbf{u} if the latter also has rank q . Otherwise, it's an approximation which grows more accurate as we let q grow towards p , and, at any given q , it's a better approximation to \mathbf{u} than any other rank- q matrix. This, finally, is the precise sense in which factor analysis tries preserve correlations, as opposed to principal components trying to preserve variance.

To resume our algebra, define $\mathbf{d}_q^{1/2}$ as the $q \times q$ diagonal matrix of the square roots of the eigenvalues. Clearly $\mathbf{d}_q = \mathbf{d}_q^{1/2} \mathbf{d}_q^{1/2}$. So

$$\mathbf{c}_q \mathbf{d}_q \mathbf{c}_q^T = \mathbf{c}_q \mathbf{d}_q^{1/2} \mathbf{d}_q^{1/2} \mathbf{c}_q^T = (\mathbf{c}_q \mathbf{d}_q^{1/2}) (\mathbf{c}_q \mathbf{d}_q^{1/2})^T \quad (19.30)$$

So we have

$$\mathbf{u} \approx (\mathbf{c}_q \mathbf{d}_q^{1/2}) (\mathbf{c}_q \mathbf{d}_q^{1/2})^T \quad (19.31)$$

⁶We could also talk about the columns; it wouldn't make any difference.

but at the same time we know that $\mathbf{u} = \mathbf{w}^T \mathbf{w}$. So we just identify \mathbf{w} with $(\mathbf{c}_q \mathbf{d}_q^{1/2})^T$:

$$\mathbf{w} = (\mathbf{c}_q \mathbf{d}_q^{1/2})^T \quad (19.32)$$

and we are done with our algebra.

Let's think a bit more about how well we're approximating \mathbf{v} . The approximation will always be exact when $q = p$, so that there is one factor for each feature (in which case $\psi = 0$ always). Then all factor analysis does for us is to rotate the coordinate axes in feature space, so that the new coordinates are uncorrelated. (This is the same as what PCA does with p components.) The approximation can *also* be exact with fewer factors than features if the reduced covariance matrix is of less than full rank, and we use at least as many factors as the rank.

19.4.3 Estimating Factor Loadings and Specific Variances

The classical method for estimating the factor model is now simply to do this eigen-vector approximation on the *sample* correlation matrix. Define the **reduced** or **adjusted** sample correlation matrix as

$$\hat{\mathbf{u}} = \hat{\mathbf{v}} - \hat{\psi} \quad (19.33)$$

We can't actually calculate $\hat{\mathbf{u}}$ until we know, or have a guess as to, $\hat{\psi}$. A reasonable and common starting-point is to do a linear regression of each feature j on all the other features, and then set $\hat{\psi}_j$ to the mean squared error for that regression. (We'll come back to this guess later.)

Once we have the reduced correlation matrix, find its top q eigenvalues and eigenvectors, getting matrices $\hat{\mathbf{c}}_q$ and $\hat{\mathbf{d}}_q$ as above. Set the factor loadings accordingly, and re-calculate the specific variances:

$$\hat{\mathbf{w}} = (\hat{\mathbf{c}}_q \hat{\mathbf{d}}_q^{1/2})^T \quad (19.34)$$

$$\hat{\psi}_j = 1 - \sum_{r=1}^k \hat{w}_{rj}^2 \quad (19.35)$$

$$\hat{\mathbf{v}} \equiv \hat{\psi} + \hat{\mathbf{w}}^T \hat{\mathbf{w}} \quad (19.36)$$

The "predicted" covariance matrix $\hat{\mathbf{v}}$ in the last line is exactly right on the diagonal (by construction), and should be closer off-diagonal than anything else we could do with the same number of factors. However, our guess as to \mathbf{u} depended on our initial guess about ψ , which has in general changed, so we can try iterating this (i.e., re-calculating $\hat{\mathbf{c}}_q$ and $\hat{\mathbf{d}}_q$), until we converge.

19.5 Maximum Likelihood Estimation

It has probably not escaped your notice that the estimation procedure above requires a starting guess as to ψ . This makes its consistency somewhat shaky. (If we continually put in ridiculous values for ψ , there's no reason to expect that $\hat{\mathbf{w}} \rightarrow \mathbf{w}$, even

with immensely large samples.) On the other hand, we know from our elementary statistics courses that maximum likelihood estimates are generally consistent, unless we choose a spectacularly bad model. Can we use that here?

We can, but at a cost. We have so far got away with just making assumptions about the means and covariances of the factor scores \mathbf{F} . To get an actual likelihood, we need to assume something about their distribution as well.

The usual assumption is that $F_{ik} \sim \mathcal{N}(0, 1)$, and that the factor scores are independent across factors $k = 1, \dots, q$ and individuals $i = 1, \dots, n$. With this assumption, the features have a multivariate normal distribution $\vec{X}_i \sim \mathcal{N}(0, \psi + \mathbf{w}^T \mathbf{w})$. This means that the log-likelihood is

$$L = -\frac{np}{2} \log 2\pi - \frac{n}{2} \log |\psi + \mathbf{w}^T \mathbf{w}| - \frac{n}{2} \text{tr} \left((\psi + \mathbf{w}^T \mathbf{w})^{-1} \hat{\mathbf{v}} \right) \quad (19.37)$$

where tr is the **trace** of the matrix \mathbf{a} , the sum of its diagonal elements. Notice that the likelihood only involves the data through the sample covariance matrix $\hat{\mathbf{v}}$ — the actual factor scores \mathbf{F} are not needed for the likelihood.

One can either try direct numerical maximization, or use a two-stage procedure. Starting, once again, with a guess as to ψ , one finds that the optimal choice of $\psi^{1/2} \mathbf{w}^T$ is given by the matrix whose columns are the q leading eigenvectors of $\psi^{1/2} \hat{\mathbf{v}} \psi^{1/2}$. Starting from a guess as to \mathbf{w} , the optimal choice of ψ is given by the diagonal entries of $\hat{\mathbf{v}} - \mathbf{w}^T \mathbf{w}$. So again one starts with a guess about the unique variances (e.g., the residuals of the regressions) and iterates to convergence.⁷

The differences between the maximum likelihood estimates and the “principal factors” approach can be substantial. If the data appear to be normally distributed (as shown by the usual tests), then the additional efficiency of maximum likelihood estimation is highly worthwhile. Also, as we’ll see below, it is a lot easier to test the model assumptions if one uses the MLE.

19.5.1 Alternative Approaches

Factor analysis is an example of trying to approximate a full-rank matrix, here the covariance matrix, with a low-rank matrix, or a low-rank matrix plus some corrections, here $\psi + \mathbf{w}^T \mathbf{w}$. Such matrix-approximation problems are currently the subject of very intense interest in statistics and machine learning, with many new methods being proposed and refined, and it is very plausible that some of these will prove to work better than older approaches to factor analysis.

In particular, Kao and Van Roy (2011) have recently used these ideas to propose a new factor-analysis algorithm, which simultaneously estimates the number of factors and the factor loadings, and does so through a modification of PCA, distinct from the old “principal factors” method. In their examples, it works better than conventional approaches, but whether this will hold true generally is not clear. They do not, unfortunately, provide code.

⁷The algebra is tedious. See section 3.2 in Bartholomew (1987) if you really want it. (Note that Bartholomew has a sign error in his equation 3.16.)

19.5.2 Estimating Factor Scores

The probably the best method for estimating factor scores is the “regression” or “Thomson” method, which says

$$\hat{F}_{ir} = \sum_j X_{ij} b_{ij} \quad (19.38)$$

and seeks the weights b_{ij} which will minimize the mean squared error, $E[(\hat{F}_{ir} - F_{ir})^2]$. You can work out the b_{ij} as an exercise, assuming you know \mathbf{w} .

19.6 The Rotation Problem

Recall from linear algebra that a matrix \mathbf{o} is **orthogonal** if its inverse is the same as its transpose, $\mathbf{o}^T \mathbf{o} = \mathbf{I}$. The classic examples are rotation matrices. For instance, to rotate a two-dimensional vector through an angle α , we multiply it by

$$\mathbf{r}_\alpha = \begin{bmatrix} \cos \alpha & -\sin \alpha \\ \sin \alpha & \cos \alpha \end{bmatrix} \quad (19.39)$$

The inverse to this matrix must be the one which rotates through the angle $-\alpha$, $\mathbf{r}_\alpha^{-1} = \mathbf{r}_{-\alpha}$, but trigonometry tells us that $\mathbf{r}_{-\alpha} = \mathbf{r}_\alpha^T$.

To see why this matters to us, go back to the matrix form of the factor model, and insert an orthogonal $q \times q$ matrix and its transpose:

$$\mathbf{X} = \boldsymbol{\epsilon} + \mathbf{F}\mathbf{w} \quad (19.40)$$

$$= \boldsymbol{\epsilon} + \mathbf{F}\mathbf{o}\mathbf{o}^T \mathbf{w} \quad (19.41)$$

$$= \boldsymbol{\epsilon} + \mathbf{H}\mathbf{y} \quad (19.42)$$

We’ve changed the factor scores to $\mathbf{H} \equiv \mathbf{H}\mathbf{o}$, and we’ve changed the factor loadings to $\mathbf{y} \equiv \mathbf{o}^T \mathbf{w}$, but nothing about the features has changed *at all*. We can do as many orthogonal transformations of the factors as we like, with no observable consequences whatsoever.⁸

Statistically, the fact that different parameter settings give us the same observational consequences means that the parameters of the factor model are **unidentifiable**. The rotation problem is, as it were, the revenant of having an ill-posed problem: we thought we’d slain it through heroic feats of linear algebra, but it’s still around and determined to have its revenge.⁹

⁸Notice that the log-likelihood only involves $\mathbf{w}^T \mathbf{w}$, which is equal to $\mathbf{w}^T \mathbf{o}\mathbf{o}^T \mathbf{w} = \mathbf{y}^T \mathbf{y}$, so even assuming Gaussian distributions doesn’t let us tell the difference between the original and the transformed variables. In fact, if $\vec{F} \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$, then $\vec{F}\mathbf{o} \sim \mathcal{N}(\mathbf{0}\mathbf{o}, \mathbf{o}^T \mathbf{I}\mathbf{o}) = \mathcal{N}(\mathbf{0}, \mathbf{I})$ — in other words, the rotated factor scores still satisfy our distributional assumptions.

⁹Remember that we obtained the loading matrix \mathbf{w} as a solution to $\mathbf{w}^T \mathbf{w} = \mathbf{u}$, that is to we got \mathbf{w} as a kind of matrix square root of the reduced correlation matrix. For a real number u there are two square roots, i.e., two numbers w such that $w \times w = u$, namely the usual $w = \sqrt{u}$ and $w = -\sqrt{u}$, because $(-1) \times (-1) = 1$. Similarly, whenever we find one solution to $\mathbf{w}^T \mathbf{w} = \mathbf{u}$, $\mathbf{o}^T \mathbf{w}$ is another solution, because $\mathbf{o}\mathbf{o}^T = \mathbf{I}$. So while the usual “square root” of \mathbf{u} is $\mathbf{w} = \mathbf{d}_q^{1/2} \mathbf{c}$, for any orthogonal matrix $\mathbf{o}^T \mathbf{d}_q^{1/2} \mathbf{c}$ will always work just as well.

Mathematically, this should not be surprising at all. The factors live in a q -dimensional vector space of their own. We should be free to set up any coordinate system we feel like on that space. Changing coordinates in factor space will just require a compensating change in how factor space coordinates relate to feature space (the factor loadings matrix \mathbf{w}). That's all we've done here with our orthogonal transformation.

Substantively, this should be rather troubling. If we can rotate the factors as much as we like without consequences, how on Earth can we interpret them?

19.7 Factor Analysis as a Predictive Model

Unlike principal components analysis, factor analysis really does give us a predictive model. Its prediction is that if we draw a new member of the population and look at the vector of observables we get from them,

$$\vec{X} \sim \mathcal{N}(0, \mathbf{w}^T \mathbf{w} + \psi) \quad (19.43)$$

if we make the usual distributional assumptions. Of course it might seem like it makes a more refined, conditional prediction,

$$\vec{X} | \vec{F} \sim \mathcal{N}(F\mathbf{w}, \psi) \quad (19.44)$$

but the problem is that there is no way to guess at or estimate the factor scores \vec{F} until after we've seen \vec{X} , at which point anyone can predict X perfectly. So the actual *forecast* is given by Eq. 19.43.¹⁰

Now, without going through the trouble of factor analysis, one could always just postulate that

$$\vec{X} \sim \mathcal{N}(0, \mathbf{v}) \quad (19.45)$$

and estimate \mathbf{v} ; the maximum likelihood estimate of it is the observed covariance matrix, but really we could use any estimator of the covariance matrix. The closer our is to the true \mathbf{v} , the better our predictions. One way to think of factor analysis is that it looks for the maximum likelihood estimate, but constrained to matrices of the form $\mathbf{w}^T \mathbf{w} + \psi$.

On the plus side, the constrained estimate has a faster rate of convergence. That is, both the constrained and unconstrained estimates are consistent and will converge on their optimal, population values as we feed in more and more data, but for the same amount of data the constrained estimate is probably closer to its limiting value. In other words, the constrained estimate $\hat{\mathbf{w}}^T \hat{\mathbf{w}} + \hat{\psi}$ has less variance than the unconstrained estimate $\hat{\mathbf{v}}$.

On the minus side, maybe the true, population \mathbf{v} just can't be written in the form $\mathbf{w}^T \mathbf{w} + \psi$. Then we're getting biased estimates of the covariance and the bias will *not*

¹⁰A subtlety is that we might get to see some but not all of \vec{X} , and use that to predict the rest. Say $\vec{X} = (X_1, X_2)$, and we see X_1 . Then we could, in principle, compute the conditional distribution of the factors, $p(F|X_1)$, and use that to predict X_2 . Of course one could do the same thing using the correlation matrix, factor model or no factor model.

go away, even with infinitely many samples. Using factor analysis rather than just fitting a multivariate Gaussian means betting that either this bias is really zero, or that, with the amount of data on hand, the reduction in variance outweighs the bias.

(I haven't talked about estimated errors in the parameters of a factor model. With large samples and maximum-likelihood estimation, one could use the usual asymptotic theory. For small samples, one bootstraps as usual.)

19.7.1 How Many Factors?

How many factors should we use? All the tricks people use for the how-many-principal-components question can be tried here, too, with the obvious modifications. However, some other answers can also be given, using the fact that the factor model does make predictions, unlike PCA.

1. *Log-likelihood ratio tests* Sample covariances will almost never be exactly equal to population covariances. So even if the data comes from a model with q factors, we can't expect the tetrad equations (or their multi-factor analogs) to hold exactly. The question then becomes whether the observed covariances are compatible with sampling fluctuations in a q -factor model, or are too big for that.

We can tackle this question by using log likelihood ratio tests. The crucial observations are that a model with q factors is a special case of a model with $q + 1$ factors (just set a row of the weight matrix to zero), and that in the most general case, $q = p$, we can get *any* covariance matrix \mathbf{v} into the form $\mathbf{w}^T \mathbf{w}$. (Set $\psi = 0$ and proceed as in the "principal factors" estimation method.)

As explained in Appendix B, if $\hat{\theta}$ is the maximum likelihood estimate in a restricted model with u parameters, and $\hat{\Theta}$ is the MLE in a more general model with $r > s$ parameters, containing the former as a special case, and finally ℓ is the log-likelihood function

$$2[\ell(\hat{\Theta}) - \ell(\hat{\theta})] \rightsquigarrow \chi_{r-s}^2 \quad (19.46)$$

when the data came from the small model. The general regularity conditions needed for this to hold apply to Gaussian factor models, so we can test whether one factor is enough, two, etc.

(Said another way, adding another factor never reduces the likelihood, but the equation tells us how much to *expect* the log-likelihood to go up when the new factor really adds nothing and is just over-fitting the noise.)

Determining q by getting the smallest one without a significant result in a likelihood ratio test is fairly traditional, but statistically messy.¹¹ To raise a subject we'll return to, if the true $q > 1$ and all goes well, we'll be doing lots of hypothesis tests, and making sure this compound procedure works reliably is harder

¹¹Suppose q is really 1, but by chance that gets rejected. Whether $q = 2$ gets rejected in turn is not independent of this!

than controlling any one test. Perhaps more worrisomely, calculating the likelihood relies on distributional assumptions for the factor scores and the noises, which are hard to check for latent variables.

2. If you are comfortable with the distributional assumptions, use Eq. 19.43 to predict new data, and see which q gives the best predictions — for comparability, the predictions should be compared in terms of the log-likelihood they assign to the testing data. If genuinely new data is not available, use cross-validation.

Comparative prediction, and especially cross-validation, seems to be somewhat rare with factor analysis. There is no good reason why this should be so.

R^2 and Goodness of Fit

For PCA, we saw that R^2 depends on the sum of the eigenvalues. For factor models, the natural notion of R^2 comes rather from the sum of squared factor loadings:

$$R^2 = \frac{\sum_{j=1}^q \sum_{k=1}^p \omega_{jk}^2}{p} \quad (19.47)$$

(Remember that the factors are, by design, uncorrelated with each other, and that the entries of \mathbf{w} are the correlations between factors and observables.) People sometimes select the number of factors by looking at how much variance they “explain” — really, how much variance is kept after smoothing on to the plane. As usual with model selection by R^2 , there is little good to be said for this, except that it is fast and simple.

In particular, R^2 should not be used to assess the goodness-of-fit of a factor model. The bluntest way to see this is to simulate data which does *not* come from a factor model, fit a small number of factors, and see what R^2 one gets. This was done by Peterson (2000), who found that it was easy to get R^2 of 0.4 or 0.5, and sometimes even higher¹² The same paper surveyed values of R^2 from the published literature on factor models, and found that the typical value was also somewhere around 0.5; no doubt this was just a coincidence¹³.

Instead of looking at R^2 , it is much better to check goodness-of-fit by actually goodness-of-fit tests. We looked at some tests of multivariate goodness-of-fit in Chapter 14. In the particular case of factor models with the Gaussian assumption, we can use a log-likelihood ratio test, checking the null hypothesis that the number of factors = q against the alternative of an arbitrary multivariate Gaussian (which is the same as p factors). This test is automatically performed by `factanal` in R.

If the Gaussian assumption is dubious but we want a factor model and goodness-of-fit anyway, we can look at the difference between the empirical covariance matrix \mathbf{v} and the one estimated by the factor model, $\hat{\psi} + \hat{\mathbf{w}}^T \hat{\mathbf{w}}$. There are several notions of distance between matrices (matrix norms) which could be used as test statistics; one could also use the sum of squared differences between the entries of \mathbf{v} and those of

¹²See also <http://bactra.org/weblog/523.html> for a similar experiment, with R code.

¹³Peterson (2000) also claims that reported values of R^2 for PCA are roughly equal to those of factor analysis, but by this point I hope that none of you take that as an argument in favor of PCA.

$\hat{\psi} + \hat{\mathbf{w}}^T \hat{\mathbf{w}}$. Sampling distributions would have to come from bootstrapping, where we would want to simulate from the factor model.

19.8 Reification, and Alternatives to Factor Models

A natural impulse, when looking at something like Figure 19.1, is to **reify** the factors, and to treat the arrows **causally**: that is, to say that there really is *some* variable corresponding to each factor, and that changing the value of that variable will change the features. For instance, one might want to say that there is a real, physical variable corresponding to the factor F_1 , and that increasing this by one standard deviation will, on average, increase X_1 by 0.87 standard deviations, decrease X_2 by 0.75 standard deviations, and do nothing to the other features. Moreover, changing any of the other factors has no effect on X_1 .

Sometimes all this is even right. How can we tell when it's right?

19.8.1 The Rotation Problem Again

Consider the following matrix, call it r :

$$\begin{bmatrix} \cos 30 & -\sin 30 & 0 \\ \sin 30 & \cos 30 & 0 \\ 0 & 0 & 1 \end{bmatrix} \quad (19.48)$$

Applied to a three-dimensional vector, this rotates it thirty degrees counter-clockwise around the vertical axis. If we apply r to the factor loading matrix of the model in the figure, we get the model in Figure 19.2. Now instead of X_1 being correlated with the other variables only through one factor, it's correlated through two factors, and X_4 has incoming arrows from three factors.

Because the transformation is orthogonal, the distribution of the observations is unchanged. In particular, the fit of the new factor model to the data will be *exactly* as good as the fit of the old model. If we try to take this causally, however, we come up with a very different interpretation. The quality of the fit to the data does not, therefore, let us distinguish between these two models, and so these two stories about the causal structure of the data.

The rotation problem does not rule out the idea that checking the fit of a factor model would let us discover *how many* hidden causal variables there are.

19.8.2 Factors or Mixtures?

Suppose we have two distributions with probability densities $f_0(x)$ and $f_1(x)$. Then we can define a new distribution which is a **mixture** of them, with density $f_\alpha(x) = (1 - \alpha)f_0(x) + \alpha f_1(x)$, $0 \leq \alpha \leq 1$. The same idea works if we combine more than two distributions, so long as the sum of the **mixing weights** sum to one (as do α and $1 - \alpha$). We will look more later at mixture models, which provide a very flexible and useful way of representing complicated probability distributions. They are also a probabilistic, predictive alternative to the kind of clustering techniques we've seen

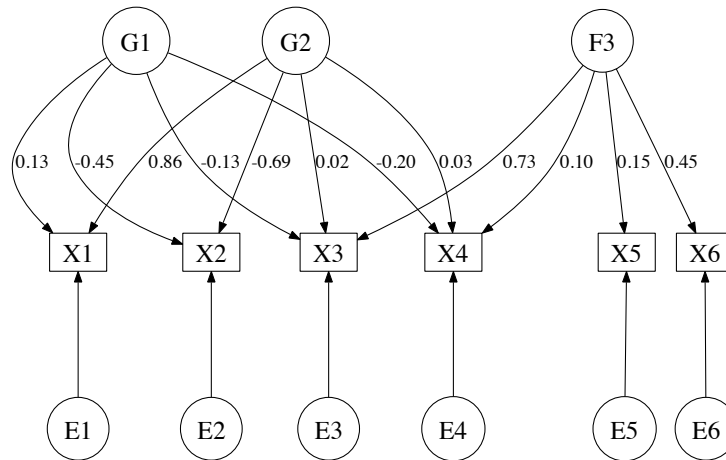

Figure 19.2: The model from Figure 19.1, after rotating the first two factors by 30 degrees around the third factor's axis. The new factor loadings are rounded to two decimal places.

before this: each distribution in the mixture is basically a cluster, and the mixing weights are the probabilities of drawing a new sample from the different clusters.¹⁴

I bring up mixture models here because there is a very remarkable result: any linear, Gaussian factor model with k factors is equivalent to some mixture model with $k + 1$ clusters, in the sense that the two models have the same means and covariances (Bartholomew, 1987, pp. 36–38). Recall from above that the likelihood of a factor model depends on the data only through the correlation matrix. If the data really were generated by sampling from $k + 1$ clusters, then a model with k factors can match the covariance matrix very well, and so get a very high likelihood. This means it will, by the usual test, seem like a very good fit. Needless to say, however, the causal interpretations of the mixture model and the factor model are very different. The two *may* be distinguishable if the clusters are well-separated (by looking to see whether the data are unimodal or not), but that's not exactly guaranteed.

All of which suggests that factor analysis can't really tell us whether we have k continuous hidden causal variables, or one discrete hidden variable taking $k + 1$ values.

¹⁴We will get into mixtures in considerable detail in the next lecture.

19.8.3 The Thomson Sampling Model

We have been working with fewer factors than we have features. Suppose that's not true. Suppose that each of our features is actually a linear combination of a *lot* of variables we don't measure:

$$X_{ij} = \eta_{ij} + \sum_{k=1}^q A_{ik} T_{kj} = \eta_{ij} + \vec{A}_i \cdot \vec{T}_j \quad (19.49)$$

where $q \gg p$. Suppose further that the latent variables A_{ik} are totally independent of one another, but they all have mean 0 and variance 1; and that the noises η_{ij} are independent of each other and of the A_{ik} , with variance ϕ_j ; and the T_{kj} are independent of everything. What then is the covariance between X_{ia} and X_{ib} ? Well, because $\mathbf{E}[X_{ia}] = \mathbf{E}[X_{ib}] = 0$, it will just be the expectation of the product of the features:

$$\mathbf{E}[X_{ia} X_{ib}] \quad (19.50)$$

$$= \mathbf{E}[(\eta_{ia} + \vec{A}_i \cdot \vec{T}_a)(\eta_{ib} + \vec{A}_i \cdot \vec{T}_b)] \quad (19.51)$$

$$= \mathbf{E}[\eta_{ia} \eta_{ib}] + \mathbf{E}[\eta_{ia} \vec{A}_i \cdot \vec{T}_b] + \mathbf{E}[\eta_{ib} \vec{A}_i \cdot \vec{T}_a] + \mathbf{E}[(\vec{A}_i \cdot \vec{T}_a)(\vec{A}_i \cdot \vec{T}_b)] \quad (19.52)$$

$$= 0 + 0 + 0 + \mathbf{E}\left[\left(\sum_{k=1}^q A_{ik} T_{ka}\right)\left(\sum_{l=1}^q A_{il} T_{lb}\right)\right] \quad (19.53)$$

$$= \mathbf{E}\left[\sum_{k,l} A_{ik} A_{il} T_{ka} T_{lb}\right] \quad (19.54)$$

$$= \sum_{k,l} \mathbf{E}[A_{ik} A_{il}] T_{ka} T_{lb} \quad (19.55)$$

$$= \sum_{k,l} \mathbf{E}[A_{ik} A_{il}] \mathbf{E}[T_{ka} T_{lb}] \quad (19.56)$$

$$= \sum_{k=1}^q \mathbf{E}[T_{ka} T_{kb}] \quad (19.57)$$

where to get the last line I use the fact that $\mathbf{E}[A_{ik} A_{il}] = 1$ if $k = l$ and $= 0$ otherwise. If the coefficients T are fixed, then the last expectation goes away and we merely have the same kind of sum we've seen before, in the factor model.

Instead, however, let's say that the coefficients T are themselves random (but independent of A and η). For each feature X_{ia} , we fix a proportion z_a between 0 and 1. We then set $T_{ka} \sim \text{Bernoulli}(z_a)$, with $T_{ka} \perp\!\!\!\perp T_{lb}$ unless $k = l$ and $a = b$. Then

$$\mathbf{E}[T_{ka} T_{kb}] = \mathbf{E}[T_{ka}] \mathbf{E}[T_{kb}] = z_a z_b \quad (19.58)$$

and

$$\mathbf{E}[X_{ia} X_{ib}] = q z_a z_b \quad (19.59)$$

Of course, in the one-factor model,

$$E[X_{ia}X_{ib}] = w_a w_b \quad (19.60)$$

So this random-sampling model looks *exactly* like the one-factor model with factor loadings proportional to z_a . The tetrad equation, in particular, will hold.

Now, it doesn't make a lot of sense to imagine that every time we make an observation we change the coefficients T randomly. Instead, let's suppose that they are first generated randomly, giving values T_{kj} , and then we generate feature values according to Eq. 19.49. The covariance between X_{ia} and X_{ib} will be $\sum_{k=1}^q T_{ka} T_{kb}$. But this is a sum of IID random values, so by the law of large numbers as q gets large this will become very close to $q z_a z_b$. Thus, for nearly all choices of the coefficients, the feature covariance matrix should come very close to satisfying the tetrad equations and looking like there's a single general factor.

In this model, each feature is a linear combination of a *random sample* of a huge pool of completely independent features, plus some extra noise specific to the feature.¹⁵ Precisely *because* of this, the features are correlated, and the pattern of correlations is that of a factor model with one factor. The appearance of a single common cause actually arises from the fact that the number of causes is immense, and there is no particular pattern to their influence on the features.

The file `thomson-model.R` (on the class website) simulates the Thomson model.

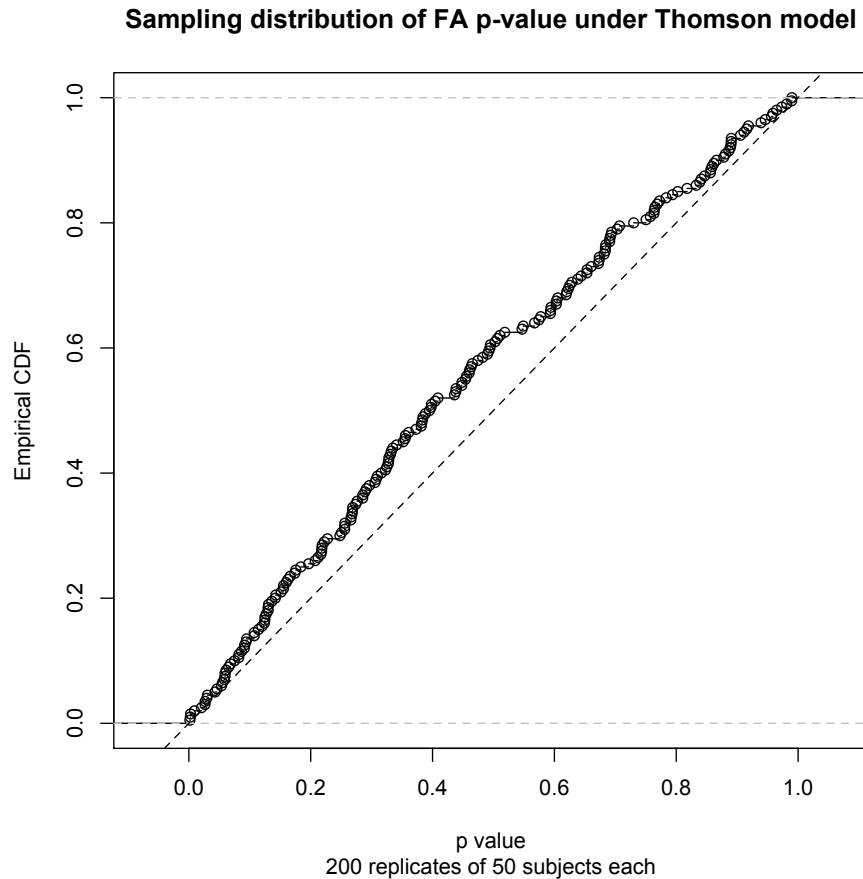

```
> tm = rthomson(50, 11, 500, 50)
> factanal(tm$data, 1)
```

The first command generates data from $n = 50$ items with $p = 11$ features and $q = 500$ latent variables. (The last argument controls the average size of the specific variances ϕ_j .) The result of the factor analysis is of course variable, depending on the random draws; my first attempt gave the proportion of variance associated with the factor as 0.391, and the p -value as 0.527. Repeating the simulation many times, one sees that the p -value is pretty close to uniformly distributed, which is what it should be if the null hypothesis is true (Figure 19.3). For fixed n , the distribution becomes closer to uniform the larger we make q . In other words, the goodness-of-fit test has little or no power against the alternative of the Thomson model.

Modifying the Thomson model to look like multiple factors grows notationally cumbersome; the basic idea however is to use multiple pools of independently-sampled latent variables, and sum them:

$$X_{ij} = \eta_{ij} + \sum_{k=1}^{q_1} A_{ik} T_{kj} + \sum_{k=1}^{q_2} B_{ik} R_{kj} + \dots \quad (19.61)$$

¹⁵When Godfrey Thomson introduced this model in 1914, he used a slightly different procedure to generate the coefficient T_{kj} . For each feature he drew a uniform integer between 1 and q , call it q_j , and then sampled the integers from 1 to q *without replacement* until he had q_j random numbers; these were the values of k where $T_{kj} = 1$. This is basically similar to what I describe, setting $z_j = q_j/q$, but a bit harder to analyze in an elementary way. — Thomson (1916), the original paper, includes what we would now call a simulation study of the model, where Thomson stepped through the procedure to produce simulated data, calculate the empirical correlation matrix of the features, and check the fit to the tetrad equations. Not having a computer, Thomson generated the values of T_{kj} with a deck of cards, and of the A_{ik} and η_{ij} by rolling 5220 dice.

```
> plot(ecdf(replicate(200, factanal(rthomson(50, 11, 500, 50)$data, 1)$PVAL)),
      xlab="p value", ylab="Empirical CDF",
      main="Sampling distribution of FA p-value under Thomson model",
      sub="200 replicates of 50 subjects each")
> abline(0, 1, lty=2)
```

Figure 19.3: Mimicry of the one-factor model by the Thomson model. The Thomson model was simulated 200 times with the parameters given above; each time, the simulated data was then fit to a factor model with one factor, and the p -value of the goodness-of-fit test extracted. The plot shows the empirical cumulative distribution function of the p -values. If the null hypothesis were exactly true, then $p \sim \text{Unif}(0, 1)$, and the theoretical CDF would be the diagonal line (dashed).

where the T_{kj} coefficients are uncorrelated with the R_{kj} , and so forth. In expectation, if there are r such pools, this *exactly* matches the factor model with r factors, and any particular realization is overwhelmingly likely to match if the q_1, q_2, \dots, q_r are large enough.¹⁶

It's not feasible to estimate the T of the Thomson model in the same way that we estimate factor loadings, because $q > p$. This is not the point of considering the model, which is rather to make it clear that we actually learn very little about where the data come from when we learn that a factor model fits well. It could mean that the features arise from combining a small number of factors, or on the contrary from combining a huge number of factors in a random fashion. A lot of the time the latter is a more plausible-sounding story.¹⁷

For example, a common application of factor analysis is in marketing: you survey consumers and ask them to rate a bunch of products on a range of features, and then do factor analysis to find attributes which summarize the features. That's fine, but it may well be that each of the features is influenced by lots of aspects of the product you don't include in your survey, and the correlations are really explained by different features being affected by many of the same small aspects of the product. Similarly for psychological testing: answering any question is really a pretty complicated process involving lots of small processes and skills (of perception, several kinds of memory, problem-solving, attention, etc.), which overlap partially from question to question.

Exercises

1. Prove Eq. 19.13.
2. Why is it fallacious to go from "the data have the kind of correlations predicted by a one-factor model" to "the data were generated by a one-factor model"?
3. Show that the correlation between the j^{th} feature and G , in the one-factor model, is w_j .
4. Check that Eq. 19.11 and Eq. 19.25 are compatible.
5. Find the weights b_{ij} for the Thomson estimator, assuming you know \mathbf{w} . Do you need to assume a Gaussian distribution?
6. Step through the examples in the accompanying R code on the class website.

¹⁶A recent paper on the Thomson model (Bartholomew *et al.*, 2009) proposes just this modification to multiple factors and to Bernoulli sampling. However, I propose this independently, in the fall 2008 version of these notes, about a year before their paper.

¹⁷Thomson (1939) remains one of the most insightful books on factor analysis, though obviously there have been a lot of technical refinements since he wrote. It's strongly recommended for anyone who plans to make much use of factor analysis. While out of print, used copies are reasonably plentiful and cheap, and at least one edition is free online (URL in the bibliography).
