Optional reading: ISL 10.3, ESL 14.3

Even more linkages

Last time we learned about **hierarchical agglomerative clustering**, basic idea is to repeatedly merge two most similar groups, as measured by the linkage

Three linkages: **single, complete, average linkage**. Properties:

- ▶ Single and complete linkage can have problems with **chaining** and **crowding**, respectively, but average linkage doesn't
- ▶ Cutting an average linkage tree provides **no interpretation**, but there is a nice interpretation for single, complete linkage trees
- ▶ Average linkage is sensitive to a **monotone transformation** of the dissimilarities d_{ij} , but single and complete linkage are not
- ▶ All three linkages produce dendograms with **no inversions**

Actually, there are many more linkages out there, each having different properties. Today: we'll look at two more

Reminder: linkages

Our setup: given $X_1, \dots, X_n$ and pairwise dissimilarities d_{ij} . (E.g., think of $X_i \in \mathbb{R}^p$ and $d_{ij} = \|X_i - X_j\|_2$)

Single linkage: measures the closest pair of points

$$d_{\text{single}}(G, H) = \min_{i \in G, j \in H} d_{ij}$$

Complete linkage: measures the farthest pair of points

$$d_{\text{complete}}(G, H) = \max_{i \in G, j \in H} d_{ij}$$

Average linkage: measures the average dissimilarity over all pairs

$$d_{\text{average}}(G, H) = \frac{1}{n_G \cdot n_H} \sum_{i \in G, j \in H} d_{ij}$$

Centroid linkage

Centroid linkage¹ is commonly used. Assume that $X_i \in \mathbb{R}^p$, and $d_{ij} = \|X_i - X_j\|_2$. Let $\bar{X}_G, \bar{X}_H$ denote group averages for G, H . Then:

$$d_{\text{centroid}}(G, H) = \|\bar{X}_G - \bar{X}_H\|_2$$

Example (dissimilarities d_{ij} are distances, groups are marked by colors): centroid linkage score $d_{\text{centroid}}(G, H)$ is the **distance between** the group centroids (i.e., group averages)

¹Eisen et al. (1998), "Cluster Analysis and Display of Genome-Wide Expression Patterns"

Centroid linkage is the standard in biology

Centroid linkage is **simple**: easy to understand, and easy to implement. Maybe for these reasons, it has become the standard for hierarchical clustering in biology

Fig. 1. Performance of a "wound response" gene expression signature in predicting breast cancer progression

Chang, Howard Y. et al. (2005) *Proc. Natl. Acad. Sci. USA* 102, 3738-3743

Centroid linkage example

Here $n = 60$, $X_i \in \mathbb{R}^2$, $d_{ij} = \|X_i - X_j\|_2$. Cutting the tree at some heights wouldn't make sense ... because the dendrogram has **inversions**! But we can, e.g., still look at output with 3 clusters

Cut interpretation: there isn't one, even with no inversions

Shortcomings of centroid linkage

- ▶ Can produce dendograms with **inversions**, which really messes up the visualization
- ▶ Even if we were lucky enough to have no inversions, still **no interpretation** for the clusters resulting from cutting the tree
- ▶ Answers change with a **monotone transformation** of the dissimilarity measure $d_{ij} = \|X_i - X_j\|_2$. E.g., changing to $d_{ij} = \|X_i - X_j\|_2^2$ would give a different clustering

Centroid?
 Say in 2D

$$\underline{\mu} = (\mu_1, \mu_2)$$

$$= \left(\frac{1}{n} \sum_{i=1}^n x_{i1}, \frac{1}{n} \sum_{i=1}^n x_{i2} \right)$$

$\underline{x}_1 = (x_{11}, x_{12})$
 $\underline{x}_2 = (x_{21}, x_{22})$
 $\vdots$
 $\underline{x}_n$

Minimax linkage

Minimax linkage² is a newcomer. First define radius of a group of points G around X_i as $r(X_i, G) = \max_{j \in G} d_{ij}$. Then:

(this is a circle, obviously -)

$$d_{\text{minimax}}(G, H) = \min_{i \in G \cup H} r(X_i, G \cup H)$$

Example (dissimilarities d_{ij} are distances, groups marked by colors): minimax linkage score $d_{\text{minimax}}(G, H)$ is the **smallest radius** encompassing all points in G and H . The center X_c is the black point

²Bien et al. (2011), "Hierarchical Clustering with Prototypes via Minimax Linkage"

Minimax linkage example

Same data as before. Cutting the tree at $h = 2.5$ gives clustering assignments marked by the colors

Cut interpretation: each point X_i belongs to a cluster whose center X_c satisfies $d_{ic} \leq 2.5$

Properties of minimax linkage

- ▶ Cutting a minimax tree at a height h a **nice interpretation**: each point is $\leq h$ in dissimilarity to the center of its cluster. (This is related to a famous set cover problem)
- ▶ Produces dendograms with **no inversions**
- ▶ Unchanged by **monotone transformation** of dissimilarities d_{ij}
- ▶ Produces clusters whose **centers are chosen among the data points** themselves. Remember that, depending on the application, this can be a very important property. (Hence minimax clustering is the analogy to K -medoids in the world of hierarchical clustering)

Example: Olivetti faces dataset

(From Bien et al. (2011))

(From Bien et al. (2011))

Centroid and minimax linkage in R

The function `hclust` in the base package performs hierarchical agglomerative clustering with centroid linkage (as well as many other linkages)

E.g.,

```
d = dist(x)
tree.cent = hclust(d, method="centroid")
plot(tree.cent)
```

The function `protoclust` in the package `protoclust` implements hierarchical agglomerative clustering with minimax linkage

Linkages summary

Linkage	No inversions?	Unchanged with monotone transformation?	Cut interpretation?	Notes
Single	✓	✓	✓	chaining
Complete	✓	✓	✓	crowding
Average	✓	✗	✗	
Centroid	✗	✗	✗	simple
Minimax	✓	✓	✓	centers are data points

Note: this doesn't tell us what "best linkage" is

What's missing here: a detailed empirical comparison of how they perform. On top of this, remember that choosing a linkage can be very **situation dependent**

Designing a clever radio system (e.g., Pandora)

Suppose we have a bunch of songs, and dissimilarity scores between each pair. We're building a clever radio system—a user is going to give us an initial song, and a measure of how “risky” he is going to be, i.e., maximal tolerable dissimilarity between suggested songs

Select a song; x_i
Select a “riskiness” r

A: Cut the tree at r

With complete,
all pairs of
songs have
dissimilarity
 $\leq r$

How could we use hierarchical clustering, and with **what linkage**?

Placing cell phone towers

Suppose we are helping to place cell phone towers on top of some buildings throughout the city. The cell phone company is looking to build a small number of towers, such that no building is further than half a mile from a tower

A: Use Minimax ; cut the tree at 0.5mi

How could we use hierarchical clustering, and with **what linkage**?

How many clusters?

Sometimes, using K -means, K -medoids, or hierarchical clustering, we might have no problem specifying the number of clusters K **ahead of time**, e.g.,

- ▶ Segmenting a client database into K clusters for K salesman
- ▶ Compressing an image using vector quantization, where K controls the compression rate

Other times, K is **implicitly defined** by cutting a hierarchical clustering tree at a given height, e.g., designing a clever radio system or placing cell phone towers

But in most exploratory applications, the number of clusters K is **unknown**. So we are left asking the question: what is the “right” value of K ?

This is a hard problem

Determining the number of clusters is a **hard problem**!

Why is it hard?

- ▶ Determining the number of clusters is a hard task for humans to **perform** (unless the data are low-dimensional). Not only that, it's just as hard to **explain** what it is we're looking for. Usually, statistical learning is successful when at least one of these is possible

Why is it important?

- ▶ E.g., it might mean a big difference scientifically if we were convinced that there were $K = 2$ subtypes of breast cancer vs. $K = 3$ subtypes
- ▶ One of the (larger) goals of data mining/statistical learning is automatic inference; choosing K is certainly part of this

Reminder: within-cluster variation

We're going to focus on K -means, but most ideas will carry over to other settings

Recall: given the number of clusters K , the K -means algorithm approximately minimizes the **within-cluster variation**:

$$W = \sum_{k=1}^K \sum_{C(i)=k} \|X_i - \bar{X}_k\|_2^2$$

Consider $K=n$
 $X_i = \bar{X}_n$
 $\vdots$
 $W = 0$

over clustering assignments C , where $\bar{X}_k$ is the average of points in group k , $\bar{X}_k = \frac{1}{n_k} \sum_{C(i)=k} X_i$

Clearly a **lower** value of W is better. So why not just run K -means for a bunch of different values of K , and choose the value of K that gives the smallest $W(K)$?

1st idea: Compact clusters are good!

That's not going to work

Problem: within-cluster variation just keeps decreasing

Example: $n = 250$, $p = 2$, $K = 1, \dots, 10$

Between-cluster variation

Within-cluster variation measures how **tightly grouped** the clusters are. As we increase the number of clusters K , this just keeps going down. What are we missing?

Between-cluster variation measures how spread apart the groups are from each other:

$$B = \sum_{k=1}^K n_k \|\bar{X}_k - \bar{X}\|_2^2$$

$\downarrow$ cluster centroid $\nwarrow$ overall data centroid

where as before $\bar{X}_k$ is the average of points in group k , and $\bar{X}$ is the overall average, i.e.

$$\bar{X}_k = \frac{1}{n_k} \sum_{C(i)=k} X_i \quad \text{and} \quad \bar{X} = \frac{1}{n} \sum_{i=1}^n X_i$$

Example: between-cluster variation

Example: $n = 100$, $p = 2$, $K = 2$

$$B = n_1 \|\bar{X}_1 - \bar{X}\|_2^2 + n_2 \|\bar{X}_2 - \bar{X}\|_2^2$$

$$W = \sum_{C(i)=1} \|X_i - \bar{X}_1\|_2^2 + \sum_{C(i)=2} \|X_i - \bar{X}_2\|_2^2$$

Still not going to work

Bigger B is better, can we use it to choose K ? Problem: between-cluster variation just keeps increasing

Running example: $n = 250$, $p = 2$, $K = 1, \dots, 10$

CH index

Ideally we'd like our clustering assignments C to **simultaneously** have a small W and a large B

This is the idea behind the **CH index**.³ For clustering assignments coming from K clusters, we record CH score:

$$\text{CH}(K) = \frac{\overset{\text{Between Cluster Variation}}{B(K)/(K-1)}}{\underset{\text{Within Cluster Variation}}{W(K)/(n-K)}} \quad \begin{array}{l} \text{# Free parameters} \\ K \text{ cluster centroids} - 1 \text{ constraint } (\bar{x}) \\ n \text{ data points cluster} \\ - K \text{ centroids} \end{array}$$

To choose K , just pick some maximum number of clusters to be considered $K_{\max}$ (e.g., $K = 20$), and choose the value of K with the largest score $\text{CH}(K)$, i.e.,

$$\hat{K} = \underset{K \in \{2, \dots, K_{\max}\}}{\operatorname{argmax}} \text{CH}(K)$$

³Calinski and Harabasz (1974), "A dendrite method for cluster analysis"

Example: CH index

Running example: $n = 250$, $p = 2$, $K = 2, \dots, 10$.

We would choose $K = 4$ clusters, which seems reasonable

General problem: the CH index is **not defined** for $K = 1$. We could never choose just one cluster (the null model)!

Gap statistic

It's true that $W(K)$ keeps dropping, but **how much it drops** at any one K should be informative

The **gap statistic**⁴ is based on this idea. We compare the observed within-cluster variation $W(K)$ to $W_{\text{unif}}(K)$, the within-cluster variation we'd see if we instead had points distributed uniformly (over an encapsulating box). The gap for K clusters is defined as

$$\text{Gap}(K) = \log W(K) - \log W_{\text{unif}}(K)$$

$$\text{Gap}(K+1) - \text{Gap}(K) = [\log(W(K+1)) - \log(W(K))] - (\log W_{\text{unif}}(K+1) - \log W_{\text{unif}}(K))$$

The quantity $\log W_{\text{unif}}(K)$ is computed by simulation: we average the log within-cluster variation over, say, 20 simulated uniform data sets. We also compute the standard error of $s(K)$ of $\log W_{\text{unif}}(K)$ over the simulations. Then we choose K by

$$\hat{K} = \min \left\{ K \in \{1, \dots, K_{\max}\} : \text{Gap}(K) \geq \text{Gap}(K+1) - s(K+1) \right\}$$

⁴Tibshirani et al. (2001), "Estimating the number of clusters in a data set via the gap statistic"

Example: gap statistic

Running example: $n = 250$, $p = 2$, $K = 1, \dots, 10$

We would choose $K = 3$ clusters, which is also reasonable

The gap statistic does especially well when the data fall into **one cluster**. (Why? Hint: think about the null distribution that it uses)

CH index and gap statistic in R

The CH index can be computed using the `kmeans` function in the base distribution, which returns both the within-cluster variation and the between-cluster variation (Homework 2)

E.g.,

```
k = 5
km = kmeans(x, k, alg="Lloyd")
names(km)
# Now use some of these return items to compute ch
```

The gap statistic is implemented by the function `gap` in the package `lga`, and by the function `gap` in the package `SAGx`. (Beware: these functions are poorly documented ... it's unclear what clustering method they're using)

Once again, it really is a hard problem

Background

Just How Many Clusters are there in the Galaxy Data?

- ▶ Galaxy Data from Postman *et al.* (1986): measurements of velocities in 10^3 km/sec of 82 galaxies from a survey of the Corona Borealis region.
- ▶ Roeder (1990): at least 3, no more than 7 modes (Confidence set)
- ▶ Others are in consensus

(Taken from George Cassella's CMU talk on January 16 2011)

Background

Modes/Clusters in the Galaxy Data: The Statistics All-Star Team

Roeder (1990)	at least 3, no more than 7 (Confidence set)
Richardson & Green (1997)	6 has highest posterior probability
Roeder & Wasserman (1997)	The posterior clearly supports three groups
Lau & Green (2007)	Optimal number of clusters is three
Wang & Dunson (2011)	Five clusters

► Anyone want to bet that there are more than SEVEN??

(From George Cassella's CMU talk on January 16 2011)

Recap: more linkages, and determining K

Centroid linkage is commonly used in biology. It measures the **distance between group averages**, and is simple to understand and to implement. But it also has some drawbacks (inversions!)

Minimax linkage is a little more complex. It asks the question: **“which point’s furthest point is closest?”**, and defines the answer as the cluster center. This could be useful for some applications

Determining the number of clusters is both a hard and important problem. We can’t simply try to find K that gives the smallest achieved within-class variation. We defined **between-cluster variation**, and saw we also can’t choose K to just maximize this

Two methods for choosing K : the **CH index**, which looks at a ratio of between to within, and the **gap statistic**, which is based on the difference between within-class variation for our data and what we’d see from uniform data

Next time: principal components analysis

Finding interesting directions in our data set
